Resonant reactions

The energy range that could be populated in the compound nucleus by capture of the incoming projectile by the target nucleus is for "direct" reactions:

- **neutron induced reactions**: M.B. energy distribution of the incoming projectile
- **charged particle reactions**: the Gamow window

If in this energy range there is an excited state (or part of it, as states have a width) then the reaction rate will have a **resonant contribution**.

If the center of the state is located in (or near) this energy range, then:
- The resonant contribution tends to dominate the reaction rate by far
- The reaction rate extremely sensitive to the properties of the resonant state
**Reaction:** \( 1 + T \rightarrow C \rightarrow F + 2 \)

For capture, \( S_1 = \gamma \) ray and \( F = C \)

- \( S_1 = \) particle 1 separation energy in \( C \)
  - Excited states above \( S_1 \) are unbound
  - can decay by emission of particle 1 (in addition to other decay modes).
  - can serve as **resonances**

For capture, \( S_1 = Q\)-value

**\( E_r \): Resonance energy** = energy needed to populate the center of a resonance state

Reminder:
- Center of mass system
- Laboratory system

\[
E_{CM} = \frac{1}{2} \mu v^2 \\
\mu = \frac{m_p m_T}{m_p + m_T}
\]

\[
E_{Lab} = \frac{1}{2} m_p v^2
\]
Breit-Wigner formula for a resonance

\[ \sigma(E) = \pi \frac{\hbar^2}{E} \cdot \omega \cdot \frac{\Gamma_1 \Gamma_2}{(E - E_r)^2 + \left(\frac{\Gamma}{2}\right)^2} \]

Usual geometric factor

\[ \frac{656.6}{A} \frac{1}{E} \text{ barn} \]

Spin factor:

\[ \omega = \frac{2J_r + 1}{(2J_p + 1)(2J_T + 1)} \]

\[ \propto \Gamma_1 \] = Partial width for decay of resonance by emission of particle 1
  = Rate for formation of compound nucleus state

\[ \propto \Gamma_2 \] = Partial width for decay of resonance by emission of particle 2
  = Rate for decay of Compound nucleus into the right exit channel

\( \Gamma \) = Total width is in the denominator as a large total width reduces the relative probabilities for formation and decay into specific channels.
Resonance contributions are on top of direct capture cross sections
...and the corresponding S-factors

Not constant S-factor for resonances (log scale !!!!)

Note varying widths!

~ constant S-factor for direct capture
Fig. 25.4. Energy levels of $^{25}$Al.
Each resonance corresponds to a level.

For example:

\[ E_r = 3.06 \text{ MeV} - 2.27 \text{ MeV} = 790 \text{ keV} \text{ in CM System!} \]

In Lab system:

\[ E_{r_{LAB}} = \frac{25}{24} \times 0.790 \text{ MeV} = 0.823 \text{ MeV} \]

So with 823 keV protons on a \(^{24}\text{Mg}\) target at rest one would hit the resonance.

Angular momentum and Parity Conservation:

\[^{24}\text{Mg}: 0^+ \]
\[ p: 1/2^+ \]

So s-wave protons can populate \(1/2^+\) resonances

p-wave protons can populate \(1/2^-\), \(3/2^-\) resonances

So the 823 keV resonance with \(3/2^-\) is a p-wave resonance.
Partial and total widths depend sensitively on the decay energy. Therefore:

- widths depend sensitively on the excitation energy of the state
- widths for a given state are a function of energy!

(they are NOT constants in the Breit Wigner Formula)

**Particle widths:**

\[ \Gamma_1 = 2P_l(E_1)\gamma^2 \]

- Main energy dependence (can be calculated)
- "reduced width"
- Contains the nuclear physics

**Photon widths:**

\[ \Gamma_\gamma = B(l) E_\gamma^{2l+1} \]

- Reduced matrix element
Partial gamma widths

- Heisenberg: $\Delta E \cdot \tau = \Gamma / \lambda = \hbar$
- $\Gamma = \lambda \hbar$
- Weiskopf estimates (see Lilley or Krane):

\[
\begin{align*}
\lambda(E1) &= 1.0 \cdot 10^{14} A^{2/3} E_\gamma^3 \\
\lambda(E2) &= 7.3 \cdot 10^7 A^{4/3} E_\gamma^5 \\
\lambda(E3) &= 34 \cdot A^2 E_\gamma^7 \\
\lambda(E4) &= 1.1 \cdot 10^{-5} A^{8/3} E_\gamma^9 \\
\lambda(M1) &= 5.6 \cdot 10^{13} E_\gamma^3 \\
\lambda(M2) &= 3.5 \cdot 10^7 A^{2/3} E_\gamma^5 \\
\lambda(M3) &= 16 \cdot A^{4/3} E_\gamma^7 \\
\lambda(M4) &= 4.5 \cdot 10^{-6} A^2 E_\gamma^9
\end{align*}
\]
For particle capture:  
\[ E_1 = E_r \quad \text{For other cases:} \quad E_1 = E_r \]
\[ E_\gamma = Q + E_r \quad E_2 = S_2 + E_r \]

Typically \( E_r << Q \) and mostly also \( E_r << S_2 \) and therefore in many cases:

- \( \Gamma_{\text{incoming particle}} \) has strong dependence on \( E_r \) (especially if it is a charged particle !)
- \( \Gamma_{\text{outgoing particle}} \) has only weak dependence on \( E_r \)

For capture of particle 1:
the main energy dependence of the cross section comes from \( \lambda^2 \) and \( \Gamma_1 \)

Particle partial widths have the same (approximate) energy dependence than the
“Penetrability” factor that we discussed in terms of the direct reaction mechanism.
### Partial widths: theoretical calculations

(Herndl et al. PRC52(95)1078)

- Weak changes in gamma width
- Strong energy dependence of proton width
In principle one has to integrate over the Breit-Wigner formula:

\[
\sigma(E) = \pi \hat{\kappa}^2 \cdot \omega \cdot \frac{\Gamma_1 \Gamma_2}{(E - E_r)^2 + (\Gamma / 2)^2}
\]

to obtain the stellar reaction rate contribution from a resonance.

There are however 2 simplifying cases:

1) a wing of a broad resonance

2) a narrow resonance
1) Rate of reaction through the wing of a broad resonance

Broad means: \( \Gamma/E_r > 10\% \)
\[ \rightarrow \text{broader than the relevant energy window for the given temperature} \]
(Gamow window for charged particle rates)

Resonances outside the energy window for the reaction can contribute as well – in fact there is in principle a contribution from the wings of all resonances.

Assume \( \Gamma_2 = \text{const}, \Gamma = \text{const} \) and use simplified

\[
\sigma(E) = \pi \lambda^2 \Gamma_1(E) \omega \frac{\Gamma_2}{(E - E_r)^2 + (\Gamma/2)^2}
\]
Proceeds mainly through tail of 0.46 MeV resonance

![Graph showing cross section as a function of lab proton energy]

**Fig. 4-4** The measured cross section for the reaction $^{12}C(p, \gamma)^{13}N$ as a function of laboratory proton energy. A four-parameter theoretical curve has been fitted to the experimental points. An extrapolation to $E_p = 0.025$ Mev, which is an interesting energy for this reaction in astrophysics, appears treacherous. (Courtesy of W. A. Fowler and J. L. Vogl.)
Tails ≈ Direct captures

Far from the resonance the contribution from wings has a similar energy dependence than the direct reaction mechanism.

\[ \sigma(E) = \pi \lambda^2 \Gamma_1(E) \frac{\Gamma_2}{(E - E_r)^2 + (\Gamma / 2)^2} \]

In particular, for s-wave neutron capture there is often a 1/\(v\) contribution at thermal energies through the tails of higher lying s-wave resonances.

Resonant tail contributions and direct contributions to the reaction rate can be parametrized in the same way (for example S-factor)

Though they look the same, direct and resonant tail contributions are different things:

- in direct reactions, no compound nucleus forms
- resonance contributions can be determined from resonance properties measured at the resonance, far away from the relevant energy range (but need to consider interference !)
2) Rate of reaction through a narrow resonance

Narrow means: \( \Gamma \ll \Delta E \)

In this case, the resonance energy must be “near” the relevant energy range \( \Delta E \) to contribute to the stellar reaction rate.

Recall:

\[
< \sigma v > = \sqrt{\frac{8}{\pi \mu}} \frac{1}{(kT)^{3/2}} \int_{0}^{\infty} \sigma(E) E e^{-\frac{E}{kT}} dE
\]

and

\[
\sigma(E) = \pi \hat{\kappa}^2 \omega \frac{\Gamma_1(E) \Gamma_2(E)}{(E - E_r)^2 + (\Gamma(E)/2)^2}
\]

For a narrow resonance assume:

- M.B. distribution \( \Phi(E) \propto E e^{-\frac{E}{kT}} \) constant over resonance \( \Phi(E) \approx \Phi(E_r) \)
- All widths \( \Gamma(E) \) constant over resonance \( \Gamma_i(E) \approx \Gamma_i(E_r) \)
- \( \hat{\kappa}^2 \) constant over resonance
Stellar reaction rate for a narrow resonance

For the contribution of a single narrow resonance to the stellar reaction rate:

\[
N_A < \sigma v > = 1.54 \cdot 10^{11} (AT_9)^{-3/2} \omega \gamma [\text{MeV}] e^{-11.605 E_r [\text{MeV}]} \cdot \frac{T_9}{\text{cm}^3} \text{s mole}^{-1}
\]

The rate is entirely determined by the “resonance strength” \( \omega \gamma \)

\[
\omega \gamma = \frac{2J_r + 1}{(2J_p + 1)(2J_T + 1)} \frac{\Gamma_1 \Gamma_2}{\Gamma}
\]

Which in turn depends mainly on the total and partial widths of the resonance at resonance energies.
Often $\Gamma = \Gamma_1 + \Gamma_2$ Then for $\Gamma_1 \ll \Gamma_2 \rightarrow \Gamma \approx \Gamma_2 \rightarrow \frac{\Gamma_1 \Gamma_2}{\Gamma} \approx \Gamma_1$

$\Gamma_2 \ll \Gamma_1 \rightarrow \Gamma \approx \Gamma_1 \rightarrow \frac{\Gamma_1 \Gamma_2}{\Gamma} \approx \Gamma_2$

And reaction rate is determined by the smaller one of the widths!
The stellar reaction rate of a nuclear reaction is determined by

- sum of direct transitions to the various bound states
- sum of all narrow resonances in the relevant energy window
- tail contribution from higher lying resonances

Or as equation: 

\[ < \sigma v >= \sum < \sigma v >_{\text{DC\rightarrow state } i} + \sum < \sigma v >_{\text{Res; } i} + < \sigma v >_{\text{tails}} \]

Caution: Interference effects are possible (constructive or destructive addition) among

- Overlapping resonances with same quantum numbers
- Same wave direct capture and resonances
Resonant rates depend on temperature

The Gamow window moves to higher energies with increasing temperature – therefore different resonances play a role at different temperatures.

Gamow Window:
- 0.1 GK: 130-220 keV
- 0.5 GK: 330-670 keV
- 1 GK: 500-1100 keV

But note: Gamow window has been defined for **direct reaction** energy dependence!

The Gamow window moves to higher energies with increasing temperature – therefore different resonances play a role at different temperatures.
Some other remarks:

• If a resonance is in or near the Gamow window it tends to dominate the reaction rate by orders of magnitude.

• As the level density increases with excitation energy in nuclei, higher temperature rates tend to be dominated by resonances, lower temperature rates by direct reactions.

• As can be seen from Eq. III.68, the reaction rate is extremely sensitive to the resonance energy. For p-capture this is due to the exp(-E_r/kT) term AND \( \Gamma_p(E) \) (Penetrability)!

As \( E_r = E_x - Q \) one needs accurate excitation energies and masses!
Complications in stellar environment

Beyond temperature and density, there are additional effects related to the extreme stellar environments that affect reaction rates.

In particular, experimental laboratory reaction rates need a (theoretical) correction to obtain the stellar reaction rates.

The most important two effects are:

1. **Thermally excited target**
   - photons can excite the target at high stellar temperatures
   - reactions can have different angular momentum and parity selection rules
   - somewhat different Q-values

2. **Electron screening**
   - atoms are fully ionized in a stellar environment
   - electron gas still shields the nucleus and affects the effective Coulomb barrier
   - reactions measured in the laboratory are also screened by the atomic electrons, but the screening effect is different.
1) Thermally excited target nuclei

Ratio of nuclei in a thermally populated excited state to nuclei in the ground state is given by the **Saha Equation**: 

\[
\frac{n_{\text{ex}}}{n_{\text{gs}}} = \frac{g_{\text{ex}}}{g_{\text{gs}}} e^{-\frac{E_x}{kT}}
\]

\[g = (2J + 1)\]

Ratios of order 1 for \(E_x \sim kT\)

In nuclear astrophysics, \(kT=1-100\) keV, which is small compared to typical level spacing in nuclei at low energies (~ MeV).

-> **usually only a very small correction**, but can play a role in select cases if:

- a low lying (~100 keV) excited state exists in the target nucleus
- temperatures are high
- the populated state has a very different rate
  (for example due to very different angular momentum or parity or if the reaction is close to threshold and the slight increase in Q-value ‘tips the scale’ to open up a new reaction channel)

The correction for this effect has to be calculated. NACRE, for example, gives a correction.
Electron screening

The nuclei in an astrophysical plasma undergoing nuclear reactions are fully ionized.

However, they are immersed in a dense electron gas, which leads to some shielding of the Coulomb repulsion between projectile and target for charged particle reactions.

Charged particle reaction rates are therefore enhanced in a stellar plasma, compared to reaction rates for bare nuclei.

The Enhancement depends on the stellar conditions

The Enhancement depends on the stellar conditions

\[
<\sigma v>_{\text{screened}} = f <\sigma v>_{\text{bare}}
\]

\[
V(r) = \frac{Z_1 Z_2 e^2}{4\pi \varepsilon_0 r} + U(r)
\]

Bare nucleus Coulomb

Extra Screening potential

(attractive so <0)

(Clayton Fig. 4-24)
Case 1: Weak Screening

**Definition of weak screening regime:**

Average Coulomb energy between ions $\ll$ thermal Energy

$$\frac{e^2 Z^2}{n^{-1/3}} \ll kT$$  (for a single dominating species)

Means:
- high temperature
- low density

(typical for example for stellar hydrogen burning)

For weak screening, each ion is surrounded by a sphere of ions and electrons that are somewhat polarized by the charge of the ion (Debye-Huckel treatment)
Weak screening

Ion under consideration (test charge)

More positive ions

More electrons

Debye Radius

Then potential around ion

$$V_1(r) = \frac{eZ}{r} e^{-r/R_D}$$

With

$$R_D = \sqrt{\frac{kT}{4\pi e^2 \rho N_A \xi^2}}$$

Exp: Quicker drop off due to screening

$\xi = \sqrt{\sum_i (Z_i^2 + Z_i \Theta_e) Y_i}$

So for $r >> R_D$ complete screening
In weak screening regime, $R_D >> (R_0 - R)$
And therefore one can assume $U(r) \sim \text{const} \sim U(0)$. 
Weak screening potential

In other words, we can expand $V(r)$ around $r=0$:

$$V_1(r) = \frac{eZ_1}{r} \left( 1 - \frac{r}{R_D} + \frac{r^2}{2R_D^2} - \cdots \right)$$

To first order

$$V(r) = eZ_2 V_1(r) = \frac{e^2 Z_1 Z_2}{r} - \frac{e^2 Z_1 Z_2}{R_D}$$

Comparison with

Yields for the screening potential:

$$V(r) = \frac{Z_1 Z_2 e^2}{r} + U(r)$$

$$U(r) = U(0) = U_0 = -\frac{e^2 Z_1 Z_2}{R_D}$$
Screening factor in weak screening

Equations III.80 and III.80.a describe a corrected Coulomb barrier for the astrophysical environment.

One can show, that the impact of the correction on the barrier penetrability and therefore on the astrophysical reaction rate can be approximated through a Screening factor $f$:

$$ f = e^{-U_0/kT} $$

In weak screening $U_0 \ll kT$ and therefore

$$ f \approx 1 - \frac{U_0}{kT} $$

Summary weak screening:

$$ \langle \sigma v \rangle_{\text{screened}} = f \langle \sigma v \rangle_{\text{bare}} $$

$$ f = 1 + 0.188 \ Z_1 Z_2 \rho^{1/2} \xi T_6^{-3/2} $$

$$ \xi = \sqrt{\sum_i \left( Z_i^2 + Z_i \Theta \right) Y_i} $$

$$ U_0 = -\frac{e^2 Z_1 Z_2}{R_D} $$
Other cases

Strong screening:
Average Coulomb energy larger than kT – for high densities and low temperatures
Again simple formalism available, for example in Clayton

Intermediate screening:
Average Coulomb energy comparable to kT – more complicated but formalisms available in literature
Screening in Laboratory Experiments

If one measures reaction rates in the laboratory, using atomic targets (always), then atomic electrons screen as well.

In the laboratory one measures screened reaction rates. BUT the screening is different from the screening in the stellar plasma.

- In the star it depends on temperature, density and composition
- In the lab it depends on the material (and temperature ?)

Measured reaction rates need to be corrected to obtain bare reaction rates. These are employed in stellar models \( \rightarrow \) screening correction in the astrophysical plasma.
In laboratory: screening potential $U_e$

\[ \frac{\sigma_{\text{screened}}}{\sigma_{\text{bare}}} = \frac{E}{E + U_e} e^{\frac{\pi \eta U_e}{E}} \]

\[ \eta = \frac{Z_1 Z_2 e^2}{h \nu} \]

Example:

$d(d,p)t$ with d-implanted Ta target

Example I: $^{14}\text{N}(p,\gamma)^{15}\text{O}$

- slowest reaction in the CNO cycle
  - Controls duration of hydrogen burning
  - Determines main sequence turnoff – glob. cluster ages

- stable target → can be measured directly:

- but cross sections are extremely low:
  - Measure as low an energy as possible
    - then extrapolate to Gamow window
Calculating experimental event rates and yields

beam of particles

$\lambda = \sigma j$

hits target at rest

area $A$

thickness $d$

assume thin target (unattenuated beam intensity throughout target)

Reaction rate (per target nucleus):

$\lambda = \sigma j$

Total reaction rate (reactions per second)

$R = \lambda A dn_T = \sigma I dn_T$

with $n_T$ : number density of target nuclei

$I = jA$ : beam number current (number of particles per second hitting the target)

Note! $dn_T$ is number of target nuclei per cm$^2$. Often the target thickness is specified in these terms.
Events detected in experiment per second $R_{\text{det}}$

$$R_{\text{det}} = R \varepsilon$$

$\varepsilon$ is the detection efficiency and can accounts for:

- detector efficiency (fraction of particles hitting a detector that produce a signal that is registered)
- solid angle limitations
- absorption losses in materials
- energy losses that cause particles energies to slide below a detection threshold
- ...

$^{14}\text{N}(p,\gamma)^{15}\text{O}$ level scheme

$E_{\text{CM}} [\text{keV}]$ → $E_X [\text{keV}]$ → $J^\pi$

- 2187 → 9484 \(3/2^+\)
- 987 → 8284 \(3/2^+\)
- 7297 → 7556 \(1/2^+\)
- 259 → 7276 \(7/2^+\)
- 6859 \(5/2^+\)
- 6791 \(3/2^+\)
- 6172 \(3/2^-\)
- 5241 \(5/2^+\)
- 5180 \(1/2^+\)

$0$ → $1/2^-$
